Either prove or give a counterexample: if  $u, v$  is an edge in an undirected graph, and during depth-first search  $\text{post}(u) < \text{post}(v)$ , then  $v$  is an ancestor of  $u$  in the DFS tree.

The only case when a vertex  $u$  can have a smaller post value than another vertex  $v$  is when there is a branching in the graph between say, vertex 1 and between vertex 2 and vertex 3. Since DFS will always pick the smallest value, and continue until there are no possible way to move forward, vertex 3 will have a higher post number than anyone in vertex 2's treeline. However, since we are confined to only  $u$  and  $v$ 's that together create an edge, this behavior will not come into play. Instead, we can only consider where there is  $u, v$  that share an edge and are explored through DFS.

Then, by the given information,  $\text{post}(u) < \text{post}(v)$  which will look like  $[? [? [ [ [ ] ] ] ]_u]_v$  where the '?'s represent unknown pre values (a vertex with a lower pre number is the ancestor).

Then  $u$  have a lower pre number than  $v$ . Then formulation look like  $[u [v [ [ [ ] ] ] ] ?]_?$ . However, backtracking after finding the  $n^{\text{th}}$  element, since in order to backtrack to  $u$ , we need to first backtrack through  $v$  we have a contradiction, it must be the case that  $[v [u [ [ [ ] ] ] ] ]_v$  which makes  $v$  and ancestor of  $u$ . **QED**
